Exploration of Shared SNPs in Thaps Chr1-qfiltered

June 29, 2017

Rambling exploration of SNP positions shared between two or more of the isolates. Code is included to document it thoroughly, (even if largely uninteresting to anyone else), and I will summarize it as I go.

1 HISTORY 2

1 History

This was added to SVN 1/26/2014; not sure when it was started, but earliest related emails I see are from 1/21/14.

```
r413 | ruzzo | 2014-01-26 08:22:37 -0800 (Sun, 26 Jan 2014) | 2 lines adding shared-snp analysis.
```

2 Preliminaries

NOTE: Some comments in code and some parts of the text, especially specific numbers and general conclusions, are based on Unqfiltered, Chr1, Medium stringency (i.e., "[[2]]" below) analysis. The broad picture does not appear to change with other choices, but details do, and the text is neither fully parameterized nor fully updated, so proceed with caution.

Load utility R code; do setup:

```
source('../../R/wlr.R') # load util code; path relative this folder or sibling in scripts/larrys
## Running as: ruzzo @ bicycle.cs.washington.edu; SVN Id, I miss you. $Id: wlr.R 2017-06-26 or later $
setup.my.wd('shared-snps') # set working dir; UPDATE if this file moves, or if COPY/PASTE to new file
setup.my.knitr('f-knitr/')
generic.setup('figs-mine/')
```

3 Major Analysis/Performance Parameters.

Choices here control how this file is processed, what data is analyzed, speed, etc. Set them carefully before running "make." Major choices are:

- 1. WHICH SNP TABLES ARE LOADED??? The logical vector load.tb selects the desired combination of SNP tables to load, in the order full.unfiltered, chrl.unfiltered, full.qfiltered, chrl.qfiltered. E.g., load.tb=(T, F, T, F) loads *full* tables for *both* q- and un-qfiltered data. Primary analysis is only performed on one of them, but the others are retained for comparison/debugging.
- 2. WHICH MAIN ANALYSIS??? If multiple tables are loaded, which is used for the main analysis? Parameter pri is a permutation of 1:4, corresponding to load.tb; the first loaded table in that order becomes the analysis focus. The default pri=c(1,2,3,4) looks at un-q-filtered data in preference to q-filtered, and full tables in preference to Chr1 within each group.
 - (Choice of data for the "Table 1" coverage summary in section 5 is independent of this; full genome data is prefered over Chr 1 for both q- and unq-filtered reads; change tset.picker calls near the end of that section to modify this.)
- 3. CLEAR CACHE??? clear.cache=T forces Knitr cache removal at the start of the run; especially important if the previous parameters have changed since the last run.
- 4. HOW MANY BOOTSTRAP REPLICATES??? The variable nboot is a major performance factor; 1000 reps takes several hours. Set to 5 for debug and quick look; 100 or more for final run.
- 5. TRUNCATE TABLES TO Chrs ONLY??? I.e., remove mitochondrial-, plastid-, and BD- contigs.

The following code chunk sets the first four parameters based on where it's run. To prototype/debug on a laptop, faster is better—run on Chr1 with small nboot; when run on the linux servers, I typically do full genomes, more replicates. Just override them if these defaults don't work for you.

```
# for Makefile, params can be command line args, else base on system; see wlr.r for details.
# load.tb order: full.un, chr1.un, full.qfil, chr1.qfil
params <- pick.params(</pre>
 mac = list(load.tb=c(F,T,F,F), pri=1:4, clear.cache=F, nboot= 1, trunc.tables=T), # quick on lap
#linux = list(load.tb=c(F,F,F,T), pri=1:4, clear.cache=F, nboot= 5, trunc.tables=T), # quick qfil on server
 linux = list(load.tb=c(T,F,T,F), pri=1:4, clear.cache=T, nboot=101, trunc.tables=T) # full on server
# Alternatively, edit/uncomment the following to override the above as needed
#params<-pick.params(default=list(load.tb=c(T,T,T,T)),pri=1:4,clear.cache=T,nboot=1000,trunc.tables=T))</pre>
print (params)
# $load.tb
# full.unf chr1.unf full.qf chr1.qf
   FALSE TRUE FALSE TRUE
# $pri
# [1] 3 4 1 2
# $clear.cache
# [1] TRUE
# $nboot
# [1] 5
# $trunc.tables
# [1] FALSE
```

CLEAR CACHE??!! Some code chunks use the knitr cache, but extent of cache consistency checks unknown. If in doubt, delete "cache/" (knitr's) directory to force rebuild. T/F set in params above will/won't force removal (actually, rename):

```
decache(params$clear.cache)
# Rename of 'cache' to 'cache81575' returned TRUE .
```

If still in doubt, also manually remove "00common/mycache/" (mine). Load the main SNP data file(s) based on the parameters set in section 3.

```
# short names to keep the following chunk compact
tb <- params$load.tb
tset <- list(NULL, NULL, NULL, NULL) # tset = 'table set'</pre>
```

```
# see wlr.R for load paths
if(tb[1]) {tset[[1]] <- load.snp.tables(use.chr1.tables = FALSE, data.name='full.tables.01.26.14')}
if(tb[2]) {tset[[2]] <- load.snp.tables(use.chr1.tables = TRUE, data.name='full.tables.01.26.14')}
# Loading ../00common/mycache/snp.tables.chr1.unqfiltered.rda ...Loaded.

if(tb[3]) {tset[[3]] <- load.snp.tables(use.chr1.tables = FALSE, data.name='full.tables.02.25.15')}
if(tb[4]) {tset[[4]] <- load.snp.tables(use.chr1.tables = TRUE, data.name='full.tables.02.25.15')}
# Loading ../00common/mycache/snp.tables.chr1.qfiltered.rda ...Loaded.
# Bandaiding qfiltered tables...</pre>
```

Grrr! I should have excluded non-Chr contigs from full genome runs. Rather than change tons of code below to add mask params, I'm just going to truncate the tables, as follows. (See notes in wlr.r::make.mask for assumptions.)

```
if(params$trunc.tables) {
  for(i in 1:4) {
    if(!is.null(tset[[i]])) {
      first.mito <- match("mitochondria.fasta", tset[[i]][[7]]$Chr)
    if(!is.na(first.mito)) { # will be NA for Chr1 tables</pre>
```

```
for(j in 1:7){
    # hmmm... slow; wonder whether head(tset[[i]][[j]], first.mito-1) is faster;
    # ok, simple tests suggest not: system.time(head(data.frame(1:1e7,1:1e7),5e6))
    tset[[i]][[j]] <- tset[[i]][[j]][1:(first.mito-1),]
    }
}
else {
    cat('***\n*** DID YOU *REALLY* WANT UNTRUNCATED TABLES???\n***\n')
}

# ***
# *** DID YOU *REALLY* WANT UNTRUNCATED TABLES???
# ***</pre>
```

The tersely-named tset list is sometimes convenient, but give them more descriptive names, too.

```
snp.tables.full.unfiltered <- tset[[1]]; names(tset)[1] <- 'snp.tables.full.unfiltered'
snp.tables.chr1.unfiltered <- tset[[2]]; names(tset)[2] <- 'snp.tables.chr1.unfiltered'
snp.tables.full.qfiltered <- tset[[3]]; names(tset)[3] <- 'snp.tables.full.qfiltered'
snp.tables.chr1.qfiltered <- tset[[4]]; names(tset)[4] <- 'snp.tables.chr1.qfiltered'</pre>
```

Main analysis may just use one of the potentially 4 table sets. Pick it according to the priority specified in section 3, using the shorter name 'snp.tables' for this default choice.

```
snp.tables <- tset.picker(priority=params$pri, table.set=tset)</pre>
```

```
# Sanity check: unlike unqfiltered tables, bug in early code gave qfiltered ones different numbers
# of rows per strain, which breaks much code. Verify this is no longer happening.
check.eq.nrows <- function(tables){</pre>
 if(!is.null(tables)){
   nrow.snp.tables <- unlist(lapply(tables,nrow))</pre>
   print (nrow.snp.tables)
   if(all(nrow.snp.tables == nrow.snp.tables[1])){
     cat('OK, all strains have same number of rows.\n')
     cat('***\n*** Warning: Different strains have different numbers of rows! ***\n***\n')
dummy<-lapply(tset, check.eq.nrows)</pre>
                           1014
                                 1015
            1012
                    1013
                                          3367 1335
# 3042585 3042585 3042585 3042585 3042585 3042585
# OK, all strains have same number of rows.
   1007 1012 1013 1014 1015 3367 1335
# 3042585 3042585 3042585 3042585 3042585 3042585
# OK, all strains have same number of rows.
```

Which tables have we got?:

```
# 'which.snp.tables' return summary of which tables, either as a char string (default), e.g.
# "Chr1-qfiltered", or as vector of 2 strings, e.g. c("full", "unfiltered").
cat('This analysis uses: (', paste(unlist(lapply(tset,which.snp.tables)),collapse=', '), ') SNP tables.\n')
# This analysis uses: ( NULL, Chr1-unfiltered, NULL, Chr1-qfiltered ) SNP tables.
cat('Main shared SNP analysis focuses on', which.snp.tables(snp.tables), '\n')
# Main shared SNP analysis focuses on Chr1-qfiltered
```

A LATEX hack: I want which snp.tables info in doc title/page headers, but it is unknown until now, so the following writes a command definition \whichsnptables into the .aux file, which is read during the next LATEX run, when \begin{document} is processed:

Subsequent analysis was initially all directed at Chr1. In general, I have *not* updated the discussion to reflect genome-wide analysis.

```
if(exists('snp.tables.chr1.qfiltered') && exists('snp.tables.chr1.unqfiltered')){
    # If have both, where is new unequal to old?
    uneq <- snp.tables.chr1.qfiltered[[1]]$Ref[1:chr1.len] != snp.tables.chr1.unqfiltered[[1]]$Ref[1:chr1.len]
    cat('Sum uneq:', sum(uneq,na.rm=T), '\n')
    cat('Sum NA: ', sum(is.na(uneq)), '\n')
    print(which(is.na(uneq))[1:10])
    seecounts(which(is.na(uneq))[1:4],snp.tables=snp.tables.qfiltered,debug=F)
}</pre>
```

In brief, "snp.tables" will be a list of 7 data frames, one per strain, giving read counts for each nucleotide at each position, SNP calls, etc.:

```
names (snp.tables)
# [1] "1007" "1012" "1013" "1014" "1015" "3367" "1335"
str(snp.tables[[1]])
# 'data.frame': 3042585 obs. of 16 variables:
  $ snp : int 0 0 0 0 0 0 0 0 0 ...
  $ Chr : chr "Chr1" "Chr1" "Chr1" "Chr1" ...
 $ Pos : int 1 2 3 4 5 6 7 8 9 10 ...
  $ Ref : chr "T" "C" "C" "A" ..
  $ Cov : num 0 2 3 4 4 4 7 8 9 10 ...
          : num 0 0 0 0 0 0 0 0 0 0 ...
  $ a
  $ g
         : num 0 0 0 0 0 0 0 0 0 0 ...
        : num 0 0 0 0 0 0 0 0 0 ...
  $ C
        : num 0 0 0 0 0 0 0 0 0 0 ...
  $ t
  $ n
         : num 0 0 0 0 0 0 0 0 0 ...
  $ .match: num 0 2 3 4 4 4 7 8 9 10 ...
  $ exon : logi FALSE FALSE FALSE FALSE FALSE ...
 $ indel : logi FALSE FALSE FALSE FALSE FALSE ...
# $ chr : Factor w/ 1 level "Chr1": 1 1 1 1 1 1 1 1 1 1 ...
         : int 1 2 3 4 5 6 7 8 9 10 ...
# $ rawCov: num 1 3 4 5 7 7 10 12 13 15 .
```

Just for background, also load the desert tables:

```
# from svn+ssh://ceg1.ocean.washington.edu/var/svn/7_strains/trunk/code/snpNB/data
#load('../../data/ungit-data/des.rda')
load('../../data/des.rda')
```

What's the total length of all deserts in each strain? Big deserts (defined as "big.threshold" or longer)?

```
some.desert.stats <- function(big.threshold=0) {</pre>
 desert.len <- unlist(lapply(des, function(x) {sum(unlist(lapply(x, function(y) {sum(y[,'Length'])}))))))))</pre>
 bigdes.len <- unlist(lapply(des, function(x) {sum(unlist(lapply(x, function(y)) {
                                                sum(y[y[,'Length']>=big.threshold,'Length'])})))))
 rbind(desert.len, desert.pct=round( desert.len / genome.length.constants()$genome.length.trunc * 100),
       bigdes.len, bigdes.pct=round( bigdes.len / genome.length.constants()$genome.length.trunc * 100))
some.desert.stats(big.threshold=50000)
                      tp1012 tp1013 tp1014 tp1015 thapsIT
# desert.len 11146526 11332566 5801763 9464213 11251426 6780300 10883723
# desert.pct
                 36
                          36
                                 19
                                         30
                                                   36
# bigdes.len 3495805 3936973
                               55365 3627235 3727061
                                                        57119 4046934
# bigdes.pct 11 13 0 12 12
```

I.e., looking at all deserts, about 1/3 of L-clade, 1/5 of H-clade are in deserts, whereas, looking at the largest deserts (> 50k), only about 12% in L-clade (and none in H-clade). Note that the rough stats above include artifactual "deserts" created by gaps in the reference sequence, large genomic deletions, etc. A more careful analysis of this is found in nc-snps.rnw.

4 Refined SNP Calls

4.1 Method

It is appropriate that SNP calls should be conservative, to avoid many false positives, but, when a position is called a SNP in one isolate, we often see a significant number of reads for the same non-reference nucleotide at that position in other isolates, even if they are not called as SNPs. On the other hand, we sometimes see a position called a SNP in two or more isolates, but with *different* pairs of nucleotides, potentially suggesting technical errors. Analysis in this section attempts to refine the SNP calls by looking for issues such as these by looking at all 7 isolates jointly, at each position called a SNP in any of them.

For a given strain, the following function returns a vector of 0:4 to indicate which nonreference nucleotide has the maximum read count at the corresponding position. The values 1..4 indicate that the max count occurred at A, G, C, T, resp. (Ties are resolved arbitrarily (a < g < c < t), which possibly deserves further attention.) The value 0 means all nonreference counts are below threshold, based *either* on absolute count *or* as a fraction of coverage. Default only excludes 0 counts.

```
nref.nuc.new <- function(strain=1, mask=T, thresh.count=0, thresh.rate=0.0){
    # get read count for max nonref nuc
    nref <- apply(snp.tables[[strain]][mask, c('a', 'g', 'c', 't')], 1, max)
    # where does nref count match a (g,c,t, resp) count
    as <- ifelse(nref == snp.tables[[strain]][mask,'a'],1,0)
    gs <- ifelse(nref == snp.tables[[strain]][mask,'g'],2,0)
    cs <- ifelse(nref == snp.tables[[strain]][mask,'c'],3,0)
    ts <- ifelse(nref == snp.tables[[strain]][mask,'t'],4,0)
    # most positions will show 3 zeros and one of 1:4, so max identifies max nonref count;
    # ties broken arbitrarily (a<g<c<t)
    merge <- pmax(as,gs,cs,ts)
    # but if max nonref count is zero or below threshold, return 0
    merge[nref == 0 | nref < thresh.count] <- 0
    merge[nref/snp.tables[[strain]][mask,'Cov'] < thresh.rate] <- 0
    return(merge)
}</pre>
```

Get union and intersection of the sets of called SNPs. ("\$snp" is 0/1.) Also, 5-way (L-clade) and 4-way (L-excluding Gyre).

```
# 4-way union/intersection
u4.snps <- snp.tables[[1]]$snp
i4.snps <- snp.tables[[1]]$snp</pre>
for(i in c(2,5,7)) {
        u4.snps <- pmax(u4.snps, snp.tables[[i]]$snp)
        i4.snps <- pmin(i4.snps, snp.tables[[i]]$snp)</pre>
# 5-way: add gyre
u5.snps <- pmax(u4.snps, snp.tables[[4]]$snp)
i5.snps <- pmin(i4.snps, snp.tables[[4]]$snp)
# 7-way
union.snps <- pmax(u5.snps, snp.tables[[3]]$snp, snp.tables[[6]]$snp)
intersect.snps <- pmin(i5.snps, snp.tables[[3]]$snp, snp.tables[[6]]$snp)</pre>
nu4snps <- sum(u4.snps)</pre>
nu5snps <- sum(u5.snps)
ni4snps <- sum(i4.snps)
ni5snps <- sum(i5.snps)</pre>
nusnps <- sum(union.snps)
nisnps <- sum(intersect.snps)</pre>
c(n4u=nu4snps, n5u=nu5snps, n7u=nusnps, n4i=ni4snps, n5i=ni5snps, n7i=nisnps)
```

```
# n4u n5u n7u n4i n5i n7i
# 18564 18696 47499 14365 7628 1641
```

There are nusnps=47499 positions called as SNPs in one or more strains (but only nisnps=1641 that are shared among all 7). Note that the 4-way union is only modestly larger (1.2923077 times larger) than the 4-way intersection, emphasizing the inherent similarities among these SNP sets. The corresponding 5-way numbers show that Gyre adds relatively little to the 5-way union vs the 4-way union, whereas it removes a fair bit from the 5-way intersection. However, much of that loss is simply because Gyre has fewer called SNPs: only 8331 vs 14365 in the 4-way intersection, and they are highly concordant:

```
sum(snp.tables[[4]]$snp*i4.snps)/sum(snp.tables[[4]]$snp)
# [1] 0.9156164
```

So, a likely source of the Gyre's difference in called SNPs is technical (lower read coverage, higher read error rate) rather than biological.

Inclusion of the 2 H-clade members, however, causes more dramatic changes in both union and intersection numbers. I examine all these relationships in more detail below, but first I examine what I believe to be a significant source of technical error in these comparisons—erroneous SNP calls, especially false negative calls.

It is appropriate that SNP calls should be conservative, to avoid many false positives, but, if a position is called a SNP in one strain, we often see a significant number of reads for the same non-reference nucleotide at that position in other strains, even if they are not called as SNPs. For my purposes below, these will be considered "shared SNPs," based on three different levels of permissiveness. Note that, e.g., $\geq 84\%$ of all positions have zero reads for any non-reference nucleotide, and only a small fraction have 2 or more non-reference reads:

```
nonmatch <- rbind(</pre>
  unlist(lapply(snp.tables, function(x) {sum(x$Cov-x$.match == 0)})),
  unlist(lapply(snp.tables, function(x) {sum(x$Cov-x$.match == 1)})),
  unlist(lapply(snp.tables, function(x){sum(x$Cov-x$.match == 2)})),
  unlist(lapply(snp.tables, function(x) {sum(x$Cov-x$.match == 3)})),
  unlist(lapply(snp.tables, function(x) {sum(x$Cov-x$.match >= 4)})),
 unlist(lapply(snp.tables, function(x){sum((x$Cov-x$.match)[union.snps==0] >= 4)}))
)/nrow(snp.tables[[1]]) *100
rownames (nonmatch) <- c('% ==0','% ==1','% ==2','% ==3','% >=4', '% >=4, nonSNP')
nonmatch
                      1007
                                  1012
                                              1013
                                                          1014
                                                                      1015
                                                                                  3367
                                                                                              1335

```

Build a table of max non-reference nucleotides at each position in the union.snps set. The three criteria are

- [[1]]: any non-zero count at any coverage is considered significant
- [[2]]: (count ≥ 2 and count/coverage ≥ 0.05) is considered significant
- [[3]]: (count > 4 and count/coverage > 0.10) is considered significant

In all three cases, the nonref nucleotide must also be consistent across all strains passing that threshold; see below.

```
non.refs[[1]][,j] <- nref.nuc.new(j, mask=union.snps==1, thresh.count=0, thresh.rate=0.00)
non.refs[[2]][,j] <- nref.nuc.new(j, mask=union.snps==1, thresh.count=2, thresh.rate=0.05)
non.refs[[3]][,j] <- nref.nuc.new(j, mask=union.snps==1, thresh.count=4, thresh.rate=0.10)
}</pre>
```

For comparison, I want to look at unfiltered SAMTools SNP calls. In complete opposition to the measures of consistency imposed above, I'm going to simply force this into the "non.refs" structure constructed above by imagining that any position called a SNP in any strain has its max nonref count on "A", so any given position called a SNP in any strain will automatically be declared "consistent." This will allow the tree-code, etc. given below to work in a uniform way (even though interpretation of the results is different.) Results will be jammed into a 4th component of the "non.refs" list; i.e., we have a 4th criterion:

• [[4]]: all called SNPs at a given position are considered "consistent."

As this case was a late addition to the analysis, the commentary throughout this document has not necessarily been updated to reflect that this case is distinct from the first three.

```
for(j in 1:7){
  non.refs[[4]][,j] <- snp.tables[[j]]$snp[union.snps==1]
}</pre>
```

"non.refs" indicates, among those positions in the union of all called SNPS having any non-reference read count above the thresholds listed above, the non-ref nucleotide having the highest read count in each strain. If, for a given position, the max of this code is the same as the min (among non-zero values), then every strain having over-threshold nonref reads in that position, in fact has most non-reference reads on the *same* nucleotide. These are defined as the "consistent" SNPs.

```
find.consistent <- function(nr) {
  nr.max <- apply(nr,1,max)
  nr.min <- apply(nr,1,function(x) {ifelse(max(x)==0,0,min(x[x>0]))})
  return(nr.min == nr.max)
}
consistent <- lapply(non.refs, find.consistent)</pre>
```

4.2 Save them

```
get.snp.locs.char = function(strain, stringency=2){
           # return char vector of locations of consistent SNPs @ specified stringency & strain
           snps <- filtered.snps$Code$get.snps(strain, stringency)</pre>
           return (names (snps) [snps])
         get.snp.locs.df = function(strain, stringency=2){
           # return data frame (Chr/Pos) of locations of consistent SNPs @ specified stringency & strain
          snplist <- strsplit(filtered.snps$Code$get.snp.locs.char(strain, stringency), ':', fixed=TRUE)</pre>
           # strsplit returns long list of 2-vectors, 1st=chr, 2nd=char position
                                          unlist(lapply(snplist, function(x) {return(x[1])})),
           df <- data.frame(Chr=
                            Pos=as.integer(unlist(lapply(snplist, function(x){return(x[2])}))),
                            stringsAsFactors = FALSE)
           return (df)
       )
# dont't clobber existing .rda, but save if absent. (delete to re-save)
rda.filtered <- paste('../00common/mycache/filtered.snps', which.snp.tables(), 'rda', sep='.')
if(file.exists(rda.filtered)){
 cat('Pre-existing file', rda.filtered, 'unchanged.\n')
} else {
 cat('Saving', rda.filtered, '...')
 save(filtered.snps, file=rda.filtered, compress=TRUE)
 cat('Saved.\n')
# Pre-existing file ../00common/mycache/filtered.snps.Chr1-qfiltered.rda unchanged.
```

Knitr seems to be failing to format the long char string above, which says:

```
cat (filtered.snps$Description)
# Contents of this .rda file:
    * Description: this text
   \star Data -- 5 items defining filtered SNPs, at 4 different stringency levels, as defined
     in shared-snps.rnw:
      * based.on.which.snp.tables: {"Chr1","full","trunc"}-{"unfiltered","qfiltered"},
       depending on which snp tables were used to build this data. ("trunc" = all Chrs.)
      * number.union.snps: the total number of SNPs (SAMtools calls) in the union of SNPs
       across all 7 strains.
      * number.intersection.snps: similar, for the 7-way intersection.
       nusnps/nisnps are easily recalculated from the data below, but their inclusion
       may be convenient, e.g., to quickly see if the .rda represents the full genome
        (nusnps=488848), or the chr 1 subset (nusnps=47499); (redundant with "based.on...";
       numbers above are for unfiltered, perhaps slightly different if qfiltered)
      \star non.ref.nucleotide: 4 arrays, each nusnps x 7, of values 0..4 (0..1 in the 4th
        array). In the 1st 3 arrays, 0 means the given position in the given strain did
       not have nonreference read counts above the corresponding filtering threshold,
       i.e., is NOT a filtered SNP in that strain, whereas 1..4 mean that it did pass
        threshold, for A,C,G,T resp. In the 4th array, this value is just 1/0,
        indicating is/is not a called SNP in that strain.
      * consistent.snps: 4 Bool vectors of length nusnps flagging positions whose nonref
       nucs (wrt to the 4 filtering criteria) are deemed *consistent* across
        all 7 strains. For the 1st 3, this means all nonzero entries of non.ref.nuc
      are equal, i.e., nonref read counts passing threshold are on the SAME nonref
```

```
# nucleotide in all strains having over-threshold counts. Just for comparison
and uniformity of data structures, the 4th is all TRUE, i.e., union of SNPs
# across all strains, without any regard for thresholds or consistency.

# In short, the filtered SNPs according to our medium filtering criteria are
# strains/positions where consistent.snps[[2]]==TRUE and non.ref.nucleotide[[2]]>0.

# Rownames in both non.ref.nucs and consistent define location, e.g. "Chr1:333".

# * Code -- simple routines to extract filtered SNPs in (potentially) convenient formats:

# * get.snps(strain, stringency=2)
# returns nusnps x 1 Bool vector of consistent SNPs @ specified stringency in
# given strain

# * get.snp.locs.char(strain, stringency=2)
# returns n x 1 char vector of locations of consistent SNPs @ specified stringency
# in given strain, e.g. "Chr1:1234", where n == sum(get.snps(...))

# * get.snp.locs.df(strain, stringency=2) {
# As above, but returns data frame (char vector Chr, int vector Pos) with the same info.
```

```
str(consistent[[1]])

# Named logi [1:47499] TRUE FALSE TRUE TRUE TRUE ...
# - attr(*, "names")= chr [1:47499] "Chr1:333" "Chr1:417" "Chr1:435" "Chr1:438" ...
```

```
consistent.count <- unlist(lapply(consistent, sum)); consistent.count
# [1] 44905 47108 47204 47499
inconsistent.count <- consistent.count[4] - consistent.count; inconsistent.count
# [1] 2594 391 295 0
inconsistent.percent <- inconsistent.count/consistent.count[4]*100; inconsistent.percent
# [1] 5.4611676 0.8231752 0.6210657 0.0000000</pre>
```

I.e., of the 47499 positions in which a SNP is called, 44905 are consistent by my loose definition, and 47204 are consistent by my tightest definition. The increase in concordance supports the view that the loose definition is too loose. Perhaps misleadingly, these counts include positions that are "consistent SNPs" in only one strain; more below. (*TODO* I suspect, but have not yet systematically checked, that most of the rest are positions with low coverage and/or very low read counts on the mixture of non-reference nucleotides.)

4.3 Examples: Consistent

Here are a few (nonrandomly selected) prototypical consistent SNPs:

```
esnps <- names(consistent[[2]][consistent[[2]]])</pre>
\texttt{esnps2} < -\texttt{as.integer}(\texttt{unlist}(\texttt{lapply}(\texttt{strsplit}(\texttt{esnps}[\texttt{c}(7,11:13,92)], ':', \texttt{fixed=TRUE}), \texttt{function}(\texttt{x})\{\texttt{x}[2]\})))
seecounts(esnps2, snp.tables=snp.tables)

4.5 Examples: Homozygous nonref

And at some *homozygous nonreference* positions (defined to be those with nonref fraction > 0.75):

```
hnr <- lapply(snp.tables, function(x) {x$.match/x$Cov < 0.25})  # find them
hnr <- lapply(hnr, function(x) {ifelse(is.na(x), FALSE, x)})  # remove NA
unlist(lapply(hnr, sum))  # count per strain</pre>
# 1007 1012 1013 1014 1015 3367 1335
```

```
# 316 247 12082 938 236 13863 167
```

Hmm, in L-clade, excluding the ref isolate (1335) this tracks time-in culture to some degree; Maybe many of these are in hemizygous regions. Next two chunks lifted from nc-snps to get tables for hemi-deletion.

```

Quick look at coverage. Are there any NA?:

Seemingly no. What's average in unq- vs q-filtered:

```
snp.tables.unqfil <- tset.picker(c(1,2), table.set = tset)
snp.tables.qfil <- tset.picker(c(3,4), table.set = tset)
cov.unqfil <- unlist(lapply(snp.tables.unqfil, function(x) {mean(x$Cov)}))
cov.qfil <- unlist(lapply(snp.tables.qfil, function(x) {mean(x$Cov,na.rm=T)}))
cov.both <- rbind(cov.unqfil,cov.qfil,cov.qfil/cov.unqfil)
i <- 1
if(!is.null(snp.tables.unqfil)){
   rownames(cov.both)[i] <- which.snp.tables(snp.tables.unqfil)
   i <- i+1
}
if(!is.null(snp.tables.qfil)){
   rownames(cov.both)[i] <- which.snp.tables(snp.tables.qfil)
   i <- i+1
}
if(i=3){
   rownames(cov.both)[i] <- 'Ratio'
}
cat('Mean Coverage:\n'); cov.both</pre>
```

```

6 Shared-SNPs P-Value

Text of the main paper quotes a "p-value" for the observed degree of SNP sharing in L-clade (and/or L-clade excluding Gyre) under a null model that these isolates were sampled from a population globally in Hardy-Weinberg equilibrium. Details of this analysis are as follows.

6.1 SNP Concordance

Arbitrarily pick one isolate, say, A, as the "template". Arbitrarily pick a heterozygous (aka "SNP") position in A. Let p_1 , and $q_1 = 1 - p_1$ be the frequencies in the overall population of the two nucleotides observed at that position in A. (Positions having 3 or 4 nucleotide variants segregating in the population are assumed to be negligibly rare.) Under the HWE null model, a second isolate B will also be heterozygous at the same position with probability $2p_1q_1 \le 1/2$. Similarly, this position will be heterozygous in a third isolate C with the same probability, *independently*, and so on for isolates D and E. Overall, (assuming HWE) the probability that a heterozygous position in A is simultaneously heterozygous in the other 4 isolates is at most $1/2^4 = 1/16$. Continuing, suppose we pick a second heterozygous position in A, on a different chromosome with allele frequencies $p_2, q_2 = 1 - p_2$, say. Again assuming HWE, this position will be a SNP in all of B, C, D and E with probability $(2p_2q_2)^4 \le 1/16$, and this is independent of the first position, since segregation on different chromosomes is unlinked. Repeat this at 24 heterozygous positions in A, one per chromosome. Then, the number of five-way concordant positions observed should be dominated by the number observed when sampling from a binomial distribution with parameters n = 24 and p = 1/16, i.e., we expect at most 1/16 = 6.25% of positions to agree, or at most 24/16 = 1.5 five-way concordant positions in total. In sharp contrast,

choosing CCMP 1014 (North Pacific Gyre) as the template, we see many more five-way concordant positions than predicted under these assumptions:

```
gyre.count <- sum(snp.tables[[4]]$snp)
# 'unfil.' => unfiltered for consistency; see below.
unfil.fiveway.count <- sum( snp.tables[[4]]$snp * i4.snps)
unfil.fiveway.percent <- unfil.fiveway.count / gyre.count * 100
unfil.p.value <- pbinom(floor(unfil.fiveway.count/gyre.count*24)-1, 24, 1/16, lower.tail = FALSE)
consistency.comparison <-
    data.frame(
        fiveway.count = unfil.fiveway.count,
        fiveway.percent = unfil.fiveway.percent,
        p.value = unfil.p.value
    )
consistency.comparison

# fiveway.count fiveway.percent p.value
# 1 7628 91.56164 8.700771e-23</pre>
```

Namely, 8331 positions are called as SNPs in CCMP1014, of which 7628 or 91.5616373% are also called as SNPs in *all four* other L-clade isolates. 91.5616373% of 24 is 21.9747929, and the probability of seeing 21 or more "Heads" in 24 flips of a biased coin with $P(\text{Heads}) \leq 1/16$, i.e., our p-value under the HWE null hypothesis, is at most: 8.700771×10^{-23} based on this simple binomial model. This is obviously strong evidence against the null hypothesis. This analysis is potentially overly-simplistic in four respects, addressed below.

- 1. " $2pq \le 1/2$ " is conservative. Neutral theory predicts that most variant nucleotides are rare in the population, so $2pq \ll 1/2$ is to be expected. This should make our quoted p-value very conservative.
- 2. Effect of Erroneous SNP calls. We base our analysis on *predicted* (by SAMTOOLS) heterozygous positions, not absolute-truth, which may affect our conclusions. However,
 - False negatives in A are irrelevant, since we never examine those positions. (This is the motivation for using CCMP1014 as the template; it has the lowest predicted SNP rate, likely due to a high false negative rate in that sequencing run. As noted elsewhere, it had the lowest coverage and lowest sequence quality of the 7 isolates, both of which impare SNP calling.)
 - False negatives in *BCDE* make such positions appear *non*-concordant. For our purpose, this makes our statistic more conservative since it can only deflate a statistic that we argue is nevertheless unexpectedly large.
 - False positive calls in A are conservatively treated, as well: barring simultaneous false-positive calls in all of BCDE, such a position will appear non-concordant, again deflating the statistic. The *false* positive rates in B, C, D and E are unknown, but cannot exceed SAMTOOLS *total* positive rate, which is below 1% in all 7 isolates, suggesting a simultaneous BCDE false positive rate $< 10^{-8}$, which will have a negligible effect.
 - A potentially more serious issue is a true positive in A aligned to false positives in BCD and/or E. (I.e., a position that is polymorphic in the population and heterozygous in A, under the HWE null model is likely to be homozygous for one of the two alleles in one or more of BCDE; false positive SNP calls in all of those isolates would make the site appear concordant, i.e., provide evidence against the null model.) However, (a) my impression is that SAMTOOLS is more prone to false negative calls than to false positive calls (see Section 4), and (b) we would need a high rate of false positives to turn a truely heterozygous but non-concordant A call into a false "concordant" call—I'd expect at most half (especially given point 1 above) of BCDE to be heterozygous, but all would need to be falsely declared heterozygous. Such a high false positive rate on BCDE seems unlikely (see previous bullet), and would likely be counterbalanced by a similarly increased rate of false positives on A, which, as noted, tend to deflate our statistic (previous bullet again).
 - Systematic errors. If there were, say, a sequence-context-dependent bias in the DNA sequencing, mapping
 and/or SNP-calling that tended to suggest (or hide) a SNP at some position, we're going to systematically
 over- (or under-) estimate concordant SNPs across isolates. The discordance of called SNPs between the

L- and H-clades and within the H-clade suggests that this is not a major problem, but it is worth noting as a possibility.

3. Discordant nucleotides at "concordant" SNP positions. A "shared" SNP at a given position might be, say, G/C in one isolate vs T/C in another, reflecting an unexpected tri-allelic position in the population or a technical sequencing error. It is inappropriate to count such a "shared" SNP position as evidence against the null hypothesis, since it isn't clear that it is truely shared. Instead, I will identify such inconsistent positions, based on the "stringency [[2]]" criteria established above, and treat each as non-concordant. I.e., a position will be considered to be a "5-way concordant SNP" if and only if it was called as a SNP by SAMTOOLS (independently) in all 5 L-clade isolates, *and* shows the same dominant non-reference nucleotide in all 5, according to criteria [[2]] above. As it turns out, this correction has a very minor effect on the resulting p-value:

```
# 'unfil.' => Ignoring "consistency"; 'fil.' => Filtering for "consistency";
fil.fiveway.count <- sum((snp.tables[[4]]$snp * i4.snps)[union.snps == 1] & consistent[[2]])</pre>
fil.fiveway.percent <- fil.fiveway.count / gyre.count * 100
fil.p.value <- pbinom(floor(fil.fiveway.count/gyre.count*24)-1, 24, 1/16, lower.tail = FALSE)
# append new stats to previous table for easy comparison
consistency.comparison <-
  rbind (consistency.comparison,
       data.frame(
         fiveway.count = fil.fiveway.count,
         fiveway.percent = fil.fiveway.percent,
         p.value = fil.p.value
 )
rownames(consistency.comparison) <- c('unfiltered', 'consistency.filtered')</pre>
consistency.comparison
                     fiveway.count fiveway.percent
                                                        p.value
                               7628 91.56164 8.700771e-23
# unfiltered
                               7537
                                           90.46933 8.700771e-23
# consistency.filtered
```

In particular, it removes 1.1% of five-way consistent positions (only 91 of 7628 positions), and still shows a highly significant p-value.

4. " $P(E[X]) \neq E[P(X)]$ ". I'm expressing this poorly, but finding the p-value based on the *expected* number of concordant positions is somewhat non-standard. A more typical set-up would use the *actual* value of some statistic, then calculate the probability of observing a value that extreme (or more extreme) under the null model. The fundamental problem is that we have thousands of SNPs, but I don't see an easy way to use more than 24 of them at a time, because potential genetic linkage seemingly destroys statistical independence, which is key to most simple analyses. A somewhat more formal, but still non-standard, approach is the following. Suppose we randomly sample one SNP per chromosome and count the number X of them that are 5-way concordant. What I outlined above calculated the p-value based on E[X], the expected value of X, i.e., P(E[X]). Alternatively, we can calculate E[P(X)], the expected p-value. (They are not the same.) In effect, this averages the p-values that would be seen over many different randomly-sampled sets of 24 SNPs. This is not difficult to calculate. First, the probability that we would observe $0 \le i \le 24$ concordant positions in a sample of 24, given that 90.47% of positions are concordant follows this binomial distribution:

```
x.equals.i.distribution <- dbinom(0:24, 24, fil.fiveway.percent/100)
print(x.equals.i.distribution, digits=3)

# [1] 3.15e-25 7.19e-23 7.85e-21 5.46e-19 2.72e-17 1.03e-15 3.11e-14 7.58e-13 1.53e-11 2.58e-10
# [11] 3.68e-09 4.44e-08 4.57e-07 4.00e-06 2.98e-05 1.89e-04 1.01e-03 4.50e-03 1.66e-02 4.98e-02
# [21] 1.18e-01 2.14e-01 2.77e-01 2.28e-01 9.04e-02</pre>
```

Second, the p-value corresponding to $0 \le i \le 24$ observed concordant positions also follows a different binomial distribution:

```
p.val.of.x.equals.i <- c(1, pbinom(0:23, 24, 1/16, lower.tail = F))
print(p.val.of.x.equals.i, digits=3)

# [1] 1.00e+00 7.88e-01 4.48e-01 1.87e-01 5.95e-02 1.49e-02 3.01e-03 4.99e-04 6.90e-05 8.02e-06
# [11] 7.89e-07 6.60e-08 4.72e-09 2.87e-10 1.49e-11 6.59e-13 2.46e-14 7.66e-16 1.98e-17 4.14e-19
# [21] 6.88e-21 8.70e-23 7.88e-25 4.56e-27 1.26e-29</pre>
```

Finally, the expected (or "average") p-value is just the weighted average of the latter values, weighted by the former:

```
e.of.p.of.x <- sum(x.equals.i.distribution * p.val.of.x.equals.i)
e.of.p.of.x
# [1] 1.33456e-14</pre>
```

This is still highly significant, but weaker than the P(E[X]) analysis, basically because X < E[X] has a fair probability of occurring, and the corresponding p-value P(X) rises rapidly as X declines.

Another way to look at the numbers:

```
pvdf <- data.frame(x.density=x.equals.i.distribution,</pre>
                   x.cdf=cumsum(x.equals.i.distribution),
                   pval.of.x=p.val.of.x.equals.i)
print(pvdf, digits=4)
    x.density
                   x.cdf pval.of.x
# 1 3.155e-25 3.155e-25 1.000e+00
# 2 7.187e-23 7.219e-23 7.875e-01
# 3 7.846e-21 7.918e-21 4.476e-01

# 24 2.285e-01 9.096e-01 4.556e-27
# 25 9.037e-02 1.000e+00 1.262e-29
```

E.g., row 9 in that table says that the concordance rate (90%) is so high that a sample of 24 SNPs will almost always have 9 or more five-way concordant positions (probability of fewer is only 1.609e-11), while under the null model, seeing 9 or more is very unlikely (probability at most 6.899e-05). ***AM I OFF-BY-ONE INTERPRETING ROW 9 HERE??***

6.2 Notes

In earlier drafts, an analog of the above analysis was based on the concordance of *refined* SNPs. This now seems to me to be questionable, since the "refined" SNP calling makes SNPs called across L-clade non-independent. OTOH,

the above analysis seems valid: SAMTOOLS was run on each isolate independently, and likewise "criterion [[2]]" is evaluated independently in each strain, and is being used here solely to remove SNP predictions, not to add them. "Systematic errors" as outlined above remain a potential problem, but again discordance with/within H-clade suggests that this is of limited concern.

For completeness, I did a similar analysis including a sample of H-clade comparisons: Gyre vs Italy, NY vs Italy, NY vs Italy+Wales, and of Italy vs Wales. As expected, none of these show a statistically significant p-value, although the $\approx 40\%$ concordance in the 2-way comparisons, while < 1/2 as predicted, is a bit higher than I expected based on "neutral theory implies many rare variants." (I did not bother to include "criterion[[2]] filtering" in these calculations.)

```
# 'gi.twoway' => gyre vs italy 2-way concordance;
# 'ni.twoway' => new york vs italy 2-way concordance;
# not bothering with criterion[[2]] filtering
gi.twoway.count <- sum(snp.tables[[4]]$snp * snp.tables[[6]]$snp)</pre>
gi.twoway.percent <- gi.twoway.count / gyre.count * 100</pre>
gi.p.value <- pbinom(floor(gi.twoway.count/gyre.count*24)-1, 24, 1/2, lower.tail = FALSE)
ny.count <- sum(snp.tables[[7]]$snp)</pre>
ni.twoway.count <- sum(snp.tables[[7]]$snp * snp.tables[[6]]$snp)</pre>
ni.twoway.percent <- ni.twoway.count / ny.count * 100</pre>
ni.p.value <- pbinom(floor(ni.twoway.count/ny.count*24)-1, 24, 1/2, lower.tail = FALSE)
niw.threeway.count <- sum(snp.tables[[7]]$snp * snp.tables[[6]]$snp * snp.tables[[3]]$snp)</pre>
niw.threeway.percent <- niw.threeway.count / ny.count * 100</pre>
niw.p.value <- pbinom(floor(niw.threeway.count/ny.count*24)-1, 24, 1/4, lower.tail = FALSE)

6.3 P-Value: The Bottom Line

So, what to say in the body of the paper? E[P(X)] is highly significant, and conservative, but complex to explain. P(E[X]) is simpler to explain, but may be criticized as misleading if we aren't very careful in that explanation. I'm slightly leaning towards the last option, but want to sleep on it and draft the key sentence or two before settling.

7 Sharing

The following analysis looks at the sharing patterns among the consistent SNPs. I assume that shared SNPs reflect shared ancestry, and that SNPs accumulate slowly over time. Then, in outline, the story is consistent with what we have seen in other analyses—there seem to be 3 groups: 1013 (Wales) in one, 3367 (Italy) in another, and the other 5 in a third, with some hints as to the order of divergence. A caveat is that in a sexual population, non-shared SNPs do not immediately imply non-shared ancestry; they may merely reflect Hardy-Weinberg capturing a homozygous state

in one isolate vs the other. (Or read errors, etc.) Thus, if we are right that the H-isolates retain sex, then the large number of "private" SNPs in H may be at least partially due to HWE.

Analysis is broken into cases based on how many strains share a particular SNP.

7.1 Code

To categorize SNPs by sharing patterns, first convert the 7-way consistent sharing pattern into a 7-bit binary number, and tabulate based on that:

```
# convert (n x 7) 0-1 matrix to n vector of 0-127
tobin <- function(x) {
  bin <- integer(nrow(x)) # initialized to 0</pre>
  for(i in 1:7){
   bin <- bin*2 + as.integer(x[,i]>0)
  return (bin)
# get full set of patterns
snp.pattern.all <- lapply(non.refs,tobin)</pre>
# prune to just the consistent ones
snp.pattern <- snp.pattern.all</pre>
for(i in 1:3){
 snp.pattern[[i]][!consistent[[i]]] <- NA</pre>
# analogous to built-in ``table'' but simpler. Count entries in an integer
# vector sharing values in a (smallish) range. Result is a 2-column matrix with
# the shared values in col 1 and count of occurrences of that value in col 2.
# Out-of-range values cause subscript error.
mytable <- function(vec, therange=range(vec,na.rm=T)){</pre>
  counts <- matrix(0, nrow=therange[2]-therange[1]+1, ncol=2, dimnames=list(NULL, c('val', 'count')))</pre>
  counts[1:nrow(counts),1] <- therange[1]:therange[2]</pre>
  for(i in 1:length(vec)){
    if(!is.na(vec[i])){
      \verb|counts|| vec[i] - the range[1] + 1, 2| <- counts|| vec[i] - the range[1] + 1, 2| + 1
  return (counts)
pattern.counts < lapply (snp.pattern, function(x) {mytable(x,c(0,127))})
```

To display the results, build a data frame whose i-th row, $0 \le i \le 127$ shows one of the 128 possible sharing patterns, with counts of the numbers of consistent, shared SNPs with that pattern according to criteria c1-c3.

```
bvec <- tobitvec(i-1)</pre>
    mydf[i,'sharedBy']=sum(bvec)
    mydf[i,'tp1007']=flg(bvec[1])
    mydf[i,'tp1012']=flg(bvec[2])
   mydf[i,'tp1013']=flg(bvec[3])
    mydf[i,'tp1014']=flg(bvec[4])
    mydf[i, 'tp1015']=flg(bvec[5])
    mydf[i,'tp3367']=flg(bvec[6])
    mydf[i,'tp1335']=flg(bvec[7])
  for(i in 1:length(listOfTbls)){
    tbl <- listOfTbls[[i]]</pre>
    if(!is.null(tbl)){
     mydf[,9+i] <- tbl[,2] ## count1/2/3/4 are columns 10/11/12/13 in mydf
      #for(j in 1:length(tbl)){
      # k <- as.integer(rownames(tbl)[j]);</pre>
         mydf[k+1,9+i] \leftarrow tbl[j] ## count1/2/3 are columns 10/11/12
      #}
    }
  mydf$pat <-as.octmode(mydf$pat) # display bit pattern in octal</pre>
  return (mydf)
pat.summaries <- pat.summary(pattern.counts)</pre>
```

7.2 Sanity Checks

Some sanity checking: table sums equal to number of consistent positions?

```
all(consistent.count == apply(pat.summaries[,10:13],2,sum))
# [1] TRUE
```

More sanity checking: visually inspect a pattern with small counts, specifically pattern 12, i.e., consistent SNPs shared by only strains 1014 and 1015 (2nd and 3 rows from bottom, binary code $12 = 2^3 + 2^2$). There are only 10 such positions on Chr1. Chr1 2524239 has pattern 12 under criteria c1 and c2 but not c3; Chr1 1088766 has in c2 only. Both look good. Neither position is a *called* SNP except in 1015. However, all but 1 nonreference read agree with the called SNP (the exception being one read in Wales). Both 1014 and 1015 have at least 2 non-reference reads, comprising at least 5% of coverage, and in both strains, those reads are on the same non-reference base, satisfying criterion c2. The other strains have higher coverage and/or lower non-reference counts, so they do not satisfy c2. Position 2524239 also satisfies c1, but not c3, since 2 reads out of 35 is below the 10% threshold. (It is pattern 4 inder c3, i.e., a SNP private to 1015.) Position 1088766 is also pattern 4 under c3 (2 reads out of 56 in 1335 is below both thresholds), and it is not consistent under c1, since the single A read in 1013 is discordant with the other non-reference reads.

```

```

Position 1088766, however, in a good example of the situation that motivated this analysis—one strain has a G/C SNP and 5 of the other 6 strains have nonreference reads consistent with that SNP. Although, excluding 1015, the nonreference read counts are not high enough to justify a SNP call in any strain considered in isolation, the fact that they *consistently* agree with the 1015 SNP suggests that they are real. One alternative hypothesis is that there is some sequence-dependent bias at this locus that favors misreading a G as a C. On the other hand, one could equally well posit a shared SNP, and a locus-dependant bias that *supresses* C reads, explaining the unbalanced readout that we observe. However, it is hard to reconcile either view with the significant strain-specific patterns that we see in the shared SNPs (as seen below). I think a more likely explanation is that (a) there are some number of relatively rare SNPs present in each of the sampled populations, (b) some of these SNPs happened to be present in one or two cells of the roughly 5-10 cells that we believe constituted the founding population of the culture grown for sequencing, and (c) stochastic effects during culture growth and during sequencing may have further perturbed the apparent frequency of each variant, but the bottom line is that the above-threshold presence of consistent non-reference reads is evidence for shared SNPs at the population level (and the proportions of such reads represent estimates of the population-level frequencies of the variants, albeit a noisy estimate at any specific position).

An aside: I was curious to see whether there is any consistent pattern to positions that are called consistent SNPs in all but Italy, so I repeated the above, basically. My summary is that coverage in Italy tends to be below average in these positions, but otherwise they don't stand out. For the record:

```
abit <- snp.pattern[[2]]==125
abit[is.na(abit)]<-F
sum(abit)

# [1] 1352

rabit <- rownames(non.refs[[2]])[which(abit)]
rabits <- rabit[1:20]
cabit <- as.integer(unlist(lapply(strsplit(rabits,':',fixed=TRUE),function(x){x[2]})))
cabit</pre>
```

More sanity: there are 83 sites on Chr1 shared by zero strains in the tightest condition. (I.e., SAMTOOLS called it a SNP, but the read counts/proportions fall below our 3rd threshold). Are they due to low coverage? Seemingly yes:

```
zp3 \leftarrow snp.pattern[[3]] == 0
zr3 <- rownames(non.refs[[3]])[which(zp3)]</pre>
zc3 <- as.integer(unlist(lapply(strsplit(zr3[1:min(100,length(zr3))],':',fixed=TRUE),function(x){x[2]})))</pre>

7.3 Main Analysis

Turning to the main analysis, there is a large increase in the number of consistent positions between the loose and medium stringency levels; medium and tight are similar in most respects. The likely interpretation is that the loose criterion is including many "SNPs" induced by read errors, and that either of the tighter criteria are successfully filtering them out. In the interest of simplicity, the narrative below will focus on the shared SNPs at the medium stringency level (the "count2" column in the data frame), although the numbers for all three (sometimes all 4) are displayed. Also note that the prose and some comments in the code were based on the Chr1 analysis, and so may occasionally be off-target for the whole-genome data.

```
# Show a subset of pat.summaries, optionally with totals of count_i in last row, and optionally
# aggregating low-count rows as ``Other''
   sharedBy=c(2,4) selects SNPs shared by 2 or 4 strains,
   subset=as.octmode('35') select those with sharing pattern a subset (optionally proper) of this
    split=as.octmode('14') additionally restricts to patterns stradling split/subset minus split
   c2.thresh=42 suppresses printout of rows with count2 < 42
  restrict.to=c(0,42,127) restrict to these 3 rows
\verb|showgroup| <- \textbf{function} (\texttt{p.summ=pat.summaries}, \texttt{sharedBy=0:7}, \texttt{subset=127}, \texttt{split=NULL}, \texttt{proper.subset=F}, \\
                       total=T, c2.thresh=0, fourteenth=F, restrict.to=NULL) {
  # pick just those bit patterns that are subsets of 'subset'
  pick <- bitwAnd(0:127,bitwNot(subset)) == 0</pre>
  if (proper.subset) {
    pick[subset+1] <- F
  if(!is.null(split)){ # AND that stradle left/right subtrees
   cosplit <- bitwAnd(subset,bitwNot(split))</pre>
    pick <- pick & bitwAnd(0:127, split) !=0 & bitwAnd(0:127, cosplit) !=0</pre>
  # and have desired shareBy counts
  pick <- pick & (p.summ$sharedBy %in% sharedBy)</pre>
  # and are among the set of interest
  if(!is.null(restrict.to)){
   pick <- pick & (0:127 %in% restrict.to)
  # find rows with low counts
  pick.low <- pick & (p.summ$count2 < c2.thresh)
  # now show them
  show <- p.summ[pick & ! pick.low,]</pre>
  # rename columns just to narrow the printouts
  colnames(show) <- c('Pat','ShrBy','1007', '1012', '1013', '1014', '1015', '3367', '1335',</pre>
                       'count1', 'count2', 'count3', 'count4')
  show[,1] <- format(show[,1]) # convert octal col to char so can override in last row(2)</pre>
  nlow <- sum(pick.low)</pre>
  if(nlow > 0){
   n <- nrow(show)+1
    lows <- apply(p.summ[pick.low, 10:13], 2, sum)</pre>
    show[n,10:13] <- lows
    show[n,1:9] <- ''
    row.names(show)[n] <- 'Other'</pre>
    if(fourteenth){
      # do this: add 14th col just to hold this comment:
      show <- cbind(show,' '='', stringsAsFactors=F)</pre>
      show[n,14] <- paste('(', nlow, 'rows w/ c2 <', c2.thresh, ')')
      ## or this (looks a bit funky, but fits across page without line-wrap):
      show[n,1:8] <-c('(', nlow, 'rows', 'w/', 'c2', '<', c2.thresh, ')')
  if(total){
   n <- nrow(show)+1
    tots <- apply(show[,10:13],2,sum)
    show[n,10:13] <- tots
    show[n,1:9] <- ''
   row.names(show)[n] <- 'Total'</pre>
   if (ncol (show) ==14) {show[n, 14] <-''}</pre>
```

```
}
return(show)
}
```

First, are there any SNPs that are not "consistent SNPs?" Yes, a few in c3. As noted above, they seem to be mainly low-coverage positions.

```
showgroup(pat.summaries,0,total=F) # chr1 totals: 0 0 83

# Pat ShrBy 1007 1012 1013 1014 1015 3367 1335 count1 count2 count3 count4
# 1 0 0 9 51 468 0
```

Next, look at completely shared SNPs, those found in all 7 strains.

I.e., of the 47108 consistent positions, 6449 or 13.7% are shared by all 7 strains.

Next look at singletons, aka private SNPs—SNPs that are called in one strain and no other strain has a significant number of non-ref reads at that position. Presumably these are variants that arose in a given population after it separated from the others.

```
showgroup(pat.summaries,1) # chr1 totals: 9669 18865 19670 23574
       Pat ShrBy 1007 1012 1013 1014 1015 3367 1335 count1 count2 count3 count4

The import of shared/private SNPs changes between sexual and asexual populations. Presumably asexuals slowly gain and rarely lose private SNPs; shared ones predate separation of the lineages. In sexual lineages, however, SNPs may be rather freely "gained" or "lost," merely by recombination (converting between homo- and heterozygous in the sample we sequenced). Thus, the low private counts for the 5 L-isolates compared to the large count of het positions overall suggest that (a) they are asexual, and (b) none of them has been isolated from the others for very long (if at all). Conversely, the high counts for Italy and Wales suggest that (a) if asexual, they have been separated from each other and from the rest for a long time, but (b) if sexual, there is little surprise: we have $\approx 160 \text{K}$ SNPs shared between the two (90K just in those two (below), plus 70K shared by all 7), and $\approx 90 \text{K}$ additional positions that are het in one but not the other. These are close to, but not exactly equal to, the 1:2:1 ratios we would naively expect from two samples of a single HWE population. The most parsimonious explanation seems to be that the H-clade is sexual, but perhaps some het positions private to each population separates them.

Aside: counts of "consistent" SNPs minus these singletons yeilds count of shared SNPs:

The slightly higher count of shared positions in the medium case further supports this choice for subsequent analysis.

Next look at consistent SNPs shared between just a pair of isolates.

I.e., of the 9510 paired SNPs, 9349 or 98.3% are found between Italy and Wales, with comparatively few shared between any other pairs (only).

SNPs shared among exactly 3 isolates are relatively rare. (The 5 trios containing both Italy and Wales predominate in the loose set, probably because they share many pairs that become triples with the addition of a few read errors.)

Four-way sharing is more common, but dominated by the coastal (i.e., non-Gyre) L-clade isolates. This is likely a reflection of the strong 5-way sharing among the L-clade, from which the Gyre commonly drops out due to the lower coverage/higher error rate in that sequencing run.

Six-way sharing is also common, with the sets *ex*cluding Gyre, Italy, or Wales having the most mutually-shared SNPs.

8 Trees

So, overall, the picture looks like a long shared history (6449 7-way shared positions), followed by a split of the 5 L-isolates from the 2 H-isolates, then a long shared history in the 5 (3560 quintuples), in parallel with a long shared history in H- (9349 pairs), then separate histories in Italy and Wales (>8912 "private" SNPs in each, although again if they are sexual, many of these just reflect HWE), and very limited differentiation among the 5 L-isolates.

Branch lengths of course depend on filtering criteria used (and, of course, full vs Chr1 differ by about a factor of 10), but the tree *topology* appears to be fairly stable. Various versions are drawn below, exactly to explore how robust this story is. I think we should go with "medium stringency" SNP filtering (based on un-qfiltered reads).

NOTE: Much of this analysis make less sense for q-filtered read data, since (a) the point of the SNP filtering was to try to correct for noise in the raw reads, which may (or may not; haven't looked closely, yet) be largely fixed by qfiltering (e.g., "loose" or no SNP filtering may be more appropriate, post-q-filtering, esp. if we had re-run SAMTools to call SNPs based on the q-filtered reads), and (b) tree topology *does* appear to change, in that Gyre's coverage has been so sharply reduced by qfiltering that it clearly stands aside from the others (and that's confirmed by bootstrap), but this also seems to be clearly a technical rather than a biological artifact. SO, code below will run on q-filtered data, but *is not tuned to it*. Likewise, most comments in the prose below were made to describe the un-q-filtered data, and *are misleading and in some cases flatly wrong* for qfiltered data, but it doesn't seem worthwhile to bother with a rewrite...

Trees are coded in newick format, which doesn't seem to tolerate line-breaks; print with line-wrap:.

```
# wrap a long char string across multiple lines in printout
cat.hardwrap <- function(str,width=80) {
    while(nchar(str)>width) {
        cat(substr(str,1,width),'\n')
        str <- substr(str,width+1,nchar(str))
    }
    cat(str,'\n')
}</pre>
```

Trees are built as follows. Code for drawing, especially, is specific to the topology of the medium tree, and placement of some of the figure elements have been hand-optimized for this case; drawings for the other variants will not be as pretty.

8 TREES 36

```
# set up for tree figs
# the newick parser in ape seems to be confused by commas and parens in
  tip names, and blanks are not allowed, so replace by *, <, >, _, resp.

  return (cap)
```

Trees based on all four SNP filtering criteria are shown below. Their topologies are exactly the same, although the branch lengths are different. In all four, the length of the branch labeled "*" is probably inflated by lower coverage and higher error rate in 1014, which may mask further legitimate sharing between it and the other L-isolates. The branch lengths among the other 4 are too short for their topology to be convincing without a more rigorous analysis (e.g., a bootstrap test), but detail there is irrelevant to the story.

My sense is that the "medium" version is the best for the paper, made here and shown in Fig 1. In theory, this should look exactly like Fig 3, but something is apparently different between Knitr and direct-to-pdf. (Increasing fig.width in Knitr's chunk headers from 8 (as in the pdf call below) to 9 helps somewhat, but probably still best to make the paper fig directly rather than via Knitr.)

```

And percent of discordant SNPs:

In short, the sharing pattern observed at 7270 or 15.4% of the 47108 medium-stringency consistent SNPs positions observed across all 7 isolates are discordant with the medium tree. (The strict tree has slightly more.)

A majority of the discordant SNPs fall into one of three patterns: 6-way sharing excluding Gyre (likely a technical artifact since the low coverage in Gyre reduces our power to detect SNPs there), or 6-way sharing excluding one of

the two H-isolates (likely a reflection of sexuality in the H-clade—SNP positions in a population in Hardy-Weinberg equilibrium are fairly likely to be homozygous for the reference allele in a given individual).

```

9 Semi-Automated Tree-Building

Slightly formalizing the process above: Look for the bifurcation of the 7 strains that maximizes the number of shared SNPs *within* each side of the partition while minimizing the number and fraction of SNPs that are shared by subsets that include at least one strain on each side of the partition. The 2/5 split is the winner, with 6418 SNPs in confict with that partition (16% of the 39842 SNPs not shared by all 7; Chr1 data). The runner-up places the Gyre in a group by itself (7079 = 18% in conflict).

```

```

Comparing the 5/2 split to the second-place NPG/rest split (below), the former has fewer pattern instances in conflict with the split (6418 vs 7079), as well as somewhat more random distribution of the conflicting patterns (92 vs 62 rows), whereas the 1/6 split has the majority of its conflicts (3912 of 7079, or 55%) concentrated in one pattern—the 5 NE strains. Collectively, these seem to favor the 5/2 split as the correct "history."

```

Below is the full summary of shared SNPs that do *not* directly correspond to tree splits, e.g. deep coalescence, independent coincident mutations, false positives/false negatives in the shared SNP calls, loss of SNPs in hemizygous regions, etc. (Additionally, SAMTools' SNP calls exclude positions it judges to be homozygous, and I think it operates without regard to the reference sequence, so homozygous nonreference positions, while rare except in IT/Wales, often are not called SNPs by SAMTools, but are relevant for this analysis. Provided the position is called a SNP in some other isolate, the consistency filtering we've done above should recover it, but this is still worth keeping in mind when examining the data.)

First, here are SNPs that "coalesce" on the branch from the LCA of bcde, i.e., shared among some nonempty, proper subset of bcde other than bc or de. There are 8 such patterns: any of the 4 choose 3 trios plus any of the 4 pairs having exactly one of bc.

```

```

So, of the 13398 SNPs found both in the L- and H-clades, 48.1% have a sharing pattern consistent with the given tree structure, i.e., are found in all 7 isolates. Among the others, three patterns dominate—(i) the 6-way pattern excluding the Gyre is the largest, plausibly explained by 7-way sharing from which the Gyre drops out due to low coverage/high error rate, (ii) the 6-way excluding Italy, and (iii) ditto for Wales. Origin of the later two cases is unclear, but may partly reflect Hardy-Weinberg—some positions that are *population-level* SNPs in those isolates will be homozygous-reference in the CCMP founder cell for IT or Wales. If I take the 7-way shared SNP count (69526) as a surrogate approximating the number of population-level SNPs in either IT or Wales that are shared with the L-clade, then I might expect, based on HWE, roughly half that number to to be lost (become homozygous) in IT, and a similar number in Wales. However, the observed counts of these positions are lower by ≈ 20 K than I might have guessed from HWE, perhaps suggesting that IT and Wales are distinct populations, each with a pool of many thousand private polymorphisms.

In aggregate:

```
untreelike <-
   sg7$count2[sg7n]-sg7$count2[sg7n-1] +
  sg5$count2[sg5n]-sg5$count2[sg5n-1] +
   sg4$count2[sg4n]-sg4$count2[sg4n-1]
untreelike</pre>
```

```
# [1] 7219
consistent.count[2]
# [1] 47108
unpct <- round(untreelike/consistent.count[2]*100,1)
unpct
# [1] 15.3</pre>
```

I.e., 7219 or 15.3% of the 47108 consistent SNPs identified (by criterion 2) across all 7 isolates are discordant with the assumed tree.

Overall, based on this data, I take the following to be obvious: (a) separation of the He-isolates from the L-isolates (and from each other??), and (b) near-identity of the L-isolates. Due to the small counts, the exact topology among the L-isolates (esp. bcde) is uncertain, but *any* topology there is consistent with the asexual/clonal/global-expansion hypothesis, so there is little point in examining this subtree more carefuly. Again, we believe the (apparent) slight separation of the Gyre from the other L-isolates is largely driven by technical artifacts (lower coverage/higher error rates) in the sequencing rather than by biological effects. However, the discord between Gyre SNPs and others is the major substantive ambiguity in the offered tree. Nevertheless, in the next section we show by a bootstrap analysis that the offered placement of Gyre with respect to the other 4 L-isolates is strongly supported by the data.

9.1 Bootstrap

How robust is the inferred tree? Italy/Wales seem clearly related to each other but separate from the other 5. Likewise, the 4 coastal L-isolates seem to be closely related, with little data to separate them (and perhaps little sense in trying). So, the key question here is whether the top level bifurcation is 2/5 or NPG/6. Here, we do a simple bootstrap test (on c2 numbers only) to see whether the 2/5 split is consistently the most parsimonious.

```
n2 <- sum(pattern.counts[[2]][,2]); n2
# [1] 47108
```

Conceptually, we sample, with replacement, n2=47108 SNP positions from among the 47108 positions declared consisent SNPs according to criterion c2, and recalculate the statistics examined above to see whether the 2/5 split again minimizes conflicting sharing patterns. This resampling/calculation is repeated nboot times (set near front of file). Since all that matters is the sharing pattern, this procedure is expedited by actually sampling 47108 independent integers in the range 0:127 with probabilities proportional to the pattern counts given in column 2 of pattern.counts[[2]]. The sample is then tabulated in a 128 row table analogous to pattern.summaries, for analysis by showgroups/treepart, as above.

```
boot.sample <- sample(0:127,n2,replace=T,prob=pattern.counts[[2]][,2])
str(boot.sample)
# int [1:47108] 127 18 125 18 18 16 127 109 2 101 ...
boot.count <- mytable(boot.sample, c(0, 127))

options(o.opts)
```

Based on this, it is reasonable to claim that we are confident that the tree topology is as shown in the earlier figures, with the exception of the exact order of the splits with the 4 NE coastal isolates.

10 Notes

This section is a random brain dump of limitations of the current analysis, ideas for improvements, etc. In the main, these may not be worth doing, unless we see significant holes or get pushed by reviewers, etc, but I wanted to catalog before we forget them.

Noise: Various sources of "noise" in the data:

- 1. Read errors, low read depth perhaps fixed by medium/strict thresholding
- 2. Deep coalescence

- 3. Skew because 1335 is the reference. (Julie notes we could partially fix this by remapping based on discovered SNPs, tho that wouldn't fix gross misassembly in 1335, e.g. collapsed or misordered tandem duplicates, or segments missing in 1335 that are present in one or more other strains, etc.; much harder to fix those, let's just hope they are rare...)
- 4. Varying error rates and sequencing depth among the 7. E.g., plausibly the 1000 SNPs shared by 4 but not by Gyre are a result of lower read depth (we missed a SNP that is actually present) and/or higher error rates (causing a position to appear inconsistent in gyre) in the gyre data. I can't think of a way to correct for this effect. It might be possible, perhaps by simulation, to estimate the size of the effect and see whether it could explain ≈1000 SNPs.
- 5. Varying numbers of founder cells in the sequencing cultures. (Again, I made some attempts at modeling this, but nothing very satisfactory yet.)
- 6. Tri-allelic positions where stochastic fluctuation in sequence sampling promotes the rare allele to prominence. (Julie replies: "isn't this the same as more than one founder cell? If they are diploid there should only ever be two alleles, unless there were random and very rare, thus unlikely, trisomy events?" I agree, but it is a concrete example of an effect of multiple founders that might be important. Not sure this is the most important such effect...)
- 7. Gaps/indels alignments are likely to be of lower quality in the vicinity of an indel, so, maybe lower coverage/more SNPs. We ignored them. Does this add any systematic bias? e.g. if one strain had more indels than another, would this confound other analyses? unclear. Julie suggested a paper titled "Barking up the wrong tree-length: yada yada yada gap penalties"; maybe relevant?

Other Items/Potential To Dos:

- 1. any spacial structure to various sub-classes?
- 2. after top level split, should I reanalyze halves of partition in isolation? said another way, I think the tree-building is sensible, but not sure it's optimal.
- 3. if we believe no sex, then I think gain of SNP should be more common than loss of SNP, since the later can only happen by (a) mutation reverting to reference, (b) second mutation matching nonreference, (c) homologous repair (look for blocks of LOH), or (d) false negative e.g. from low read depth. Does tree-building appropriately weight the gain vs loss cases? (Does it even care?)
- 4. should we weight coding and/or nonsynonomous SNPs more heavily? Julie says "you do not want to weight the coding or nonsynonomous/coding SNPs because for time you want the more clock-like neutral mutations." I.e., I got this backwards. Maybe should redo tree based on noncoding SNPs only.
- 5. We could also do an actual parsimony analysis based on 2-state model (homozygous-ref vs not), but I'm not quite sure how to handle this in a mixed sex/nosex case.
- 6. Might be interesting to look at sharing just within (shared?) deserts. Given tree model above and expectation that bottleneck followed split of H- from L-clades, I would expect little or no sharing of L-clade desert SNPs with H-clade; sharing between It/Wales might suggest "desert" is actually a region under strong purifying selection (e.g. a gene); sharing/non-sharing within L-clade deserts might suggest more about evo history of the 5.

11 Appendix: Old Trees, etc.

Tangents, old stuff of historical interest at best, etc..

11.1 HWE Sharing

Tangent: As a function of nonref allele freq, assuming HWE, what is probability that nonref allele will be seen in k strains, $0 \le k \le 4$ (Fig 6).

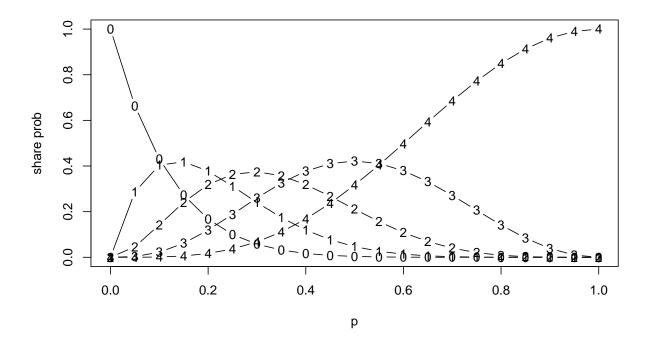

Figure 6: Sharing Probability

```
myfigpath.h <- paste(getwd(), '/figs-knitr/', sep='')

p <- (0:20)/20
q <- 1-p
r <- 2*p*q+p^2
plot( p, 1*q^0*r^4, type='b',pch='4', ylab="share prob")
points(p, 4*q^2*r^3, type='b',pch='3')
points(p, 6*q^4*r^2, type='b',pch='2')
points(p, 4*q^6*r^1, type='b',pch='1')
points(p, 1*q^8*r^0, type='b',pch='0')</pre>
```

11.2 Old Tree Stuff

All based on un-q-filtered reads.

The first pass at the tree analysis was the Chr1 tree, *loose criteria* (c1); it is rendered via http://iubio.bio.indiana.edu/treeapp/treeprint-form.html as Fig 7, and in newick format is:

```
newick.chr1.loose <- '(((tp3367_Italy:4551,tp1013_Wales:4954):5920,(((tp1007_Virginia:10,tp1012_Australia:29):9,
cat.hardwrap(newick.chr1.loose)

# (((tp3367_Italy:4551,tp1013_Wales:4954):5920,(((tp1007_Virginia:10,tp1012_Austra
# lia:29):9,(tp1015_Puget_Sound:90,tp1335_NY:13):11):320,tp1014_Gyre:22):3484):859
# 3,outgroup:0);</pre>
```

Chr 1 tree based on *medium criteria* (c2) has exactly the same topology is, although the branch lengths are different. As noted earlier, the length of the branch labeled "*" is probably inflated by lower coverage and higher error rate in 1014, which may mask further legitimate sharing between it and the other L-isloates. The branch lengths among the other 4 are too short for its topology to be convincing without a more rigorous analysis (e.g., a bootstrap test).

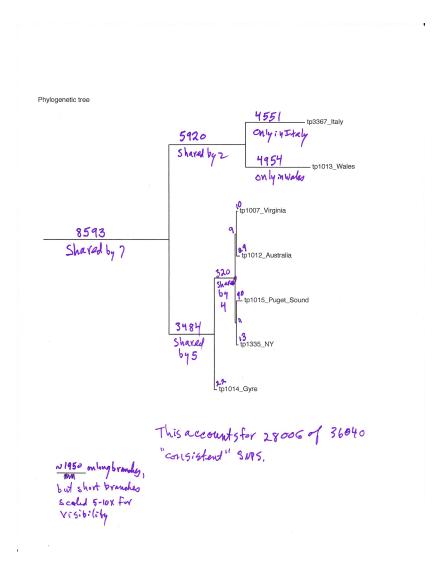

Figure 7: Inferred Tree, based on Chr1, un-q-filtered reads, loose criteria. (Note: to visually resolve the edges among the 5, their lengths were scaled by 5x - 10x in this figure, but not in the newick description shown in the text.)

Chr1 tree, medium criteria, in newick format:

```
newick.chr1.med <- '(((tp3367_Italy:8813,tp1013_Wales:9652):9365,(((e_tp1007_Virginia:30,d_tp1012_Australia:61):1
cat.hardwrap(newick.chr1.med)

# (((tp3367_Italy:8813,tp1013_Wales:9652):9365,(((e_tp1007_Virginia:30,d_tp1012_Au
# stralia:61):19,(c_tp1015_Puget_Sound:207,b_tp1335_NY:41):18):1005,a_tp1014_Gyre:
# 61):3912):7054,outgroup:0);</pre>
```

NOTE: In early code, tree was not being recalculated; it was defined by constants in the following code chunk, hand-copied from the analysis above.

```
# tree parameters as nested lists
    Internal nodes have subtrees sub1/2 and length
    Root has sub1/2, but no length
    Leaves have where, length, optionally, id, alt, nb. (Omit id for 'outgroup'. Use 'alt' for less formal labeling in cartoon version; it defaults to 'where'. Use 'nb' to add abode annotations for legend.)
# This hand-made version is now subsumed by make.tree; retained for comparison
tree.by.hand <-
  list(
    sub1 = list(
      sub1 = list(
       sub1 = list(id=3367, length=8813, where='Venice, Italy', alt='Venice'),
        sub2 = list(id=1013, length=9652, where='Wales, UK'),
        length=9365),
      sub2 = list(
        sub1 = list(
            sub1 = list(id=1007, length=30, nb='e', where='Virginia, USA'),
sub2 = list(id=1012, length=61, nb='d', where='Perth, W. Australia', alt='Perth'),
             length=19),
           sub2 = list(
            sub1 = list(id=1015, length=207,nb='c', where='Washington, USA', alt='Puget Sound'),
             sub2 = list(id=1335, length=41, nb='b', where='New York, USA',
            length=18),
          length=1005),

```

Two other versions of the tree, for possible use in figs in the main paper.

Figure 8: [** as of 10/4/2015, this fig and next have stray stars on virginia, wales labels; probably due to hacking with commas in newick; not worth fixing unless we resurrect these trees for some purpose, but if so, see use of newick.name.undo in show.tree as probable fix. **]

```
tree.scale <- ifelse(which.snp.tables(string.val=F)[1]=='Chr1', 1, 10)
tree.x.lim <- 3e4 * tree.scale
the.simple.tree <- read.tree(text=simple.newick.medium)
plot(the.simple.tree, x.lim = tree.x.lim)
axis(1)</pre>
```

Figure 9:

```
plot(the.simple.tree, x.lim = tree.x.lim)
axis(1,(0:4)*7000*tree.scale,(0:4)*7000*tree.scale)
```

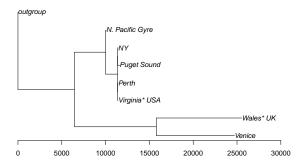

Figure 8: Tree based on qfiltered reads and medium SNP filters. "Lengths" are numbers of shared/private SNPs on Chr1. (no edge labels, nolegend)

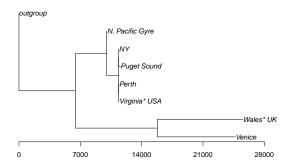

Figure 9: Tree based on qfiltered reads and medium SNP filters. "Lengths" are numbers of shared/private SNPs on Chr1. (no edge labels, no legend, short scale bar)

At some much earlier point, Tony ran the whole-genome version of the then-current code above, and manually entered tree branch lengths/legend for the resuting tree, shown in Fig 10. Code above can now automatically generate such a tree, but retain the following for comparison. The basic story seems clear—same topology and branch lengths scaled by about 10x, which is completely reasonable given that Chr1 is about 10% of the genome. Note that this tree is not being recalculated; it is defined by constants in the following code chunk.

Figure 10:

```
library(ape)
the.fullgenome.tree <- read.tree(text=fullgenome.newick.medium)
plot(the.fullgenome.tree, x.lim = fullgenome.tree.x.lim)
axis(1) #; axis(2) useful only for placing labels
opar <- par(family='mono',cex=.8)
legend('topright', legend=fullgenome.legend.text)
par(opar)
for(i in seq(1,length(fullgenome.tree.labels)-2,by=3)){
   text(fullgenome.tree.labels[[i]], fullgenome.tree.labels[[i+1]], fullgenome.tree.labels[[i+2]])
}</pre>
```

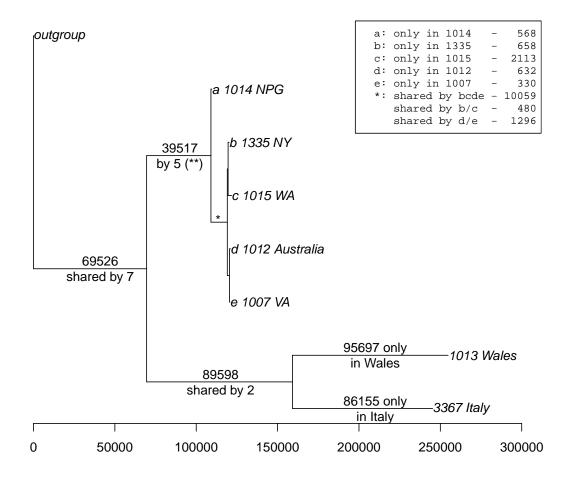

Figure 10: Tree based on unqfiltered reads and medium SNP filters. "Lengths" are numbers of shared/private SNPs genome-wide. (By-hand legacy version)
